## 1 INTRODUCTION

tbd

## 2 PRELIMINARY

#### 2.1 Basic Notations

Point and multi-point functions. Given a domain size N and Abelian group  $\mathbb{G}$ , a point function  $f_{\alpha,\beta}:[N]\to\mathbb{G}$  for  $\alpha\in[N]$  and  $\beta\in\mathbb{G}$  evaluates to  $\beta$  on input  $\alpha$  and to  $0\in\mathbb{G}$  on all other inputs. We denote by  $\hat{f}_{\alpha,\beta}=(N,\hat{\mathbb{G}},\alpha,\beta)$  the representation of such a point function. A multi-point function  $f_{A,B}:[N]\to\mathbb{G}$  for  $A=(\alpha_1,\cdots\alpha_t)\in[N]^t$  and  $B=(\beta_1,\cdots,\beta_t)\in\mathbb{G}^t$  evaluates to  $\beta_i$  on input  $\alpha_i$  for  $1\leq i\leq t$  and to 0 on all other inputs. Denote  $\hat{f}_{A,B}(N,\hat{\mathbb{G}},A,B)$  the representation of such a point function.

Enote: MPF. Also representation of groups.

# 2.2 Distributed Multi-Point Functions

#### Enote: should directly adapt to multi-point function case

We begin by defining a slightly generalized notion of distributed point functions (DPFs), which accounts for the extra parameter  $\mathbb{G}'$ .

DEFINITION 1 (DPF [1, 3]). A (2-party) distributed point function (DPF) is a triple of algorithms  $\Pi = (Gen, Eval_0, Eval_1)$  with the following syntax:

• Gen $(1^{\lambda}, \hat{f}_{\alpha,\beta}) \to (k_0, k_1)$ : On input security parameter  $\lambda \in \mathbb{N}$  and point function description  $\hat{f}_{\alpha,\beta} = (N, \hat{\mathbb{G}}, \alpha, \beta)$ , the (randomized) key generation algorithm Gen returns a pair of keys  $k_0, k_1 \in \{0, 1\}^*$ . We assume that N and  $\mathbb{G}$  are determined by each key.

Conference acronym 'XX, tbd, tbd

© tbd Association for Computing Machinery. ACM ISBN tbd...\$15.00 https://doi.org/tbd Eval<sub>i</sub>(k<sub>i</sub>, x) → y<sub>i</sub>: On input key k<sub>i</sub> ∈ {0, 1}\* and input x ∈ [N] the (deterministic) evaluation algorithm of server i, Eval<sub>i</sub> returns y<sub>i</sub> ∈ G.

We require  $\Pi$  to satisfy the following requirements:

• Correctness: For every  $\lambda$ ,  $\hat{f} = \hat{f}_{\alpha,\beta} = (N, \hat{\mathbb{G}}, \alpha, \beta)$  such that  $\beta \in \mathbb{G}$ , and  $x \in [N]$ , if  $(k_0, k_1) \leftarrow \text{Gen}(1^{\lambda}, \hat{f})$ , then

$$\Pr\left[\sum_{i=0}^{1} \mathsf{Eval}_{i}(k_{i}, x) = f_{\alpha, \beta}(x)\right] = 1$$

- Security: Consider the following semantic security challenge experiment for corrupted server i ∈ {0, 1}:
- (1) The adversary produces two point function descriptions  $(\hat{f}^0 = (N, \hat{\mathbb{G}}, \alpha_0, \beta_0), \hat{f}^1 = (N, \hat{\mathbb{G}}, \alpha_1, \beta_1)) \leftarrow \mathcal{A}(1^{\lambda})$ , where  $\alpha_i \in [N]$  and  $\beta_i \in \mathbb{G}$ .
- (2) The challenger samples  $b \leftarrow \{0, 1\}$  and  $(k_0, k_1) \leftarrow \text{Gen}(1^{\lambda}, \hat{f}^b)$ .
- (3) The adversary outputs a guess  $b' \leftarrow \mathcal{A}(k_i)$ . Denote by  $\operatorname{Adv}(1^{\lambda}, \mathcal{A}, i) = \Pr[b = b'] - 1/2$  the advantage of  $\mathcal{A}$  in guessing b in the above experiment. For every non-uniform polynomial time adversary  $\mathcal{A}$  there exists a negligible function v such that  $\operatorname{Adv}(1^{\lambda}, \mathcal{A}, i) \leq v(\lambda)$  for all  $\lambda \in \mathbb{N}$ .

We will also be interested in applying the evaluation algorithm on *all* inputs. Given a DPF (Gen, Eval<sub>0</sub>, Eval<sub>1</sub>), we denote by FullEval<sub>i</sub> an algorithm which computes  $Eval_i$  on every input x. Hence,  $FullEval_i$  receives only a key  $k_i$  as input.

#### 2.3 Batch Codes

combinatorial/probabilistic batch codes, with cuckoo hashing a concrete instantiation

## 2.4 Oblivious Key-Value Stores

DEFINITION 2 (OKVS[2, 4]). An Oblivious Key-Value Stores (OKVS) scheme is a pair of randomized algorithms (Encode<sub>r</sub>, Decode<sub>r</sub>) with respect to a statistical security parameter  $\lambda_{stat}$  and a computational security parameter  $\lambda$ , a randomness space  $\{0,1\}^\kappa$ , a key space  $\mathcal K$ , a value space  $\mathcal V$ , input length n and output length m(n). The algorithms are of the following syntax:

- Encode<sub>r</sub>({ $(k_1, v_1), (k_2, v_2), \dots, (k_n, v_n)$ })  $\rightarrow P$ : On input n key-value pairs with distinct keys, the encode algorithm with randomness r in the randomness space outputs an encoding  $P \in \mathcal{V}^m \cup \bot$ .
- Decode<sub>r</sub>(P, k) → v: On input an encoding from V<sup>m</sup> and a key k ∈ K, output a value v.

We require the scheme to satisfy

- Correctness: For every  $S \in (\mathcal{K} \times \mathcal{V})^n$ ,  $\Pr_{r \leftarrow \{0,1\}^{\kappa}} [\mathsf{Encode}_r(S) = \bot] \le 2^{-\lambda_{\mathsf{stat}}}$ .
- **Obliviousness:** Given any distinct key sets  $\{k_1^0, k_2^0, \dots, k_n^0\}$  and  $\{k_1^1, k_2^1, \dots, k_n^1\}$  that are different, if they are paired with

Conference acronym 'XX, tbd, tbd tbd

random values then their encodings are computationally indistinguishable, i.e.,

$$\{r, \mathsf{Encode}_r(\{(k_1^0, v_1), \cdots, (k_n^0, v_n)\})\}_{v_1, \cdots, v_n \leftarrow \mathcal{V}, r \leftarrow \{0, 1\}^K}$$
  
 $\approx_c \{r, \mathsf{Encode}_r(\{(k_1^1, v_1), \cdots, (k_n^1, v_n)\})\}_{v_1, \cdots, v_n \leftarrow \mathcal{V}, r \leftarrow \{0, 1\}^K}$ 

One can obtain a linear OKVS if in addition require:

• Linearity: There exists a function family  $\{\text{row}_r: \mathcal{K} \to \mathcal{V}^m\}_{r \in \{0,1\}^K}$  such that  $\mathsf{Decode}_r(P,k) = \langle \mathsf{row}_r(k), P \rangle$ .

The Encode process for a linear OKVS is the process of sampling a random P from the set of solutions of the linear system  $\{\langle \operatorname{row}_r(k_i), P \rangle = v_i\}_{1 \le i \le n}$ .

We evaluate an OKVS scheme by its encoding size (output length m), encoding time and decoding time. We stress the following two (linear) OKVS constructions:

Construction 1 (Polynomial). Suppose  $\mathcal{K} = \mathcal{V} = \mathbb{F}$  is a field. Set

- Encode({(ki, vi)}<sub>1≤i≤n</sub>) → P where P is the coefficients of a (n-1)-degree F-polynomial g<sub>P</sub> that g<sub>P</sub>(k<sub>i</sub>) = v<sub>i</sub> for 1 ≤ i ≤ n.
- Decode(P, k)  $\rightarrow g_P(k)$ .

The polynomial OKVS possesses an optimal encoding size m = n, but the Encode process is a polynomial interpolation which is only known to be achieved in time  $O(n \log^2 n)$ . The time for a single decoding is O(n) and that for batched decodings is (amortized)  $O(\log^2 n)$ .

An alternative construction that has near optimal encoding size but much better running time is as follows.

Construction 2 (3-Hash Garbled Cuckoo Table (3H-GCT)[2, 4]). Suppose  $V = \mathbb{F}$  is a field. Set  $\operatorname{row}_r(k) := \operatorname{row}_r^{\operatorname{sparse}}(k) || \operatorname{row}_r^{\operatorname{dense}}(k)$  where  $\operatorname{row}_r^{\operatorname{sparse}}$  outputs a uniformly random weight-w vector in  $\{0,1\}^{m_1}$ , and  $\operatorname{row}_r^{\operatorname{dense}}(k)$  outputs a short dense vector in  $\mathbb{F}^{m_2}$ .

- Encode( $\{(k_i, v_i)\}_{1 \le i \le n}$ )  $\rightarrow$  P where P is solved from the system  $\{\langle \mathsf{row}_r(k_i), P \rangle = v_i\}_{1 \le i \le n}$  using the triangulation algorithm in [4].
- Decode $(P, k) \rightarrow \langle row_r(k), P \rangle$ .

This OKVS construction features a linear encoding time, constant decoding time while having a linear encoding size.

TBD: Carefully(!) recompute the comparison table for OKVS and insert  $\,$ 

We take w=3, the most common option that outruns other choices of w in terms of running time. Restating the conclusion in [4]: given n and  $\lambda_{\text{stat}}$ , the choices of e and  $\hat{g}$  are  $e=1.223+\frac{\lambda_{\text{stat}}+9.2}{4.144n^{0.55}}$  and  $\hat{g}=\frac{\lambda_{\text{stat}}}{\log_2(en)}$ .

TBD: mention some connections to cuckoo hashing

## 3 NEW DMPF CONSTRUCTIONS

TBD: explain

#### 3.1 Big-State DMPF

TBD: explain

```
Set l \leftarrow t, the upperbound of |A|.
procedure Initialize(\{\text{seed}_{h}^{(0)}, \text{sign}_{h}^{(0)}\}_{b=0,1})
